Résumé — Analogues géochimiques naturels pour le stockage du dioxyde de carbone en réservoir géologique poreux profond : perspective pour le Royaume-Uni

— La concentration élevée en CO₂ atmosphérique participe au réchauffement climatique. Une mesure d'atténuation consiste à capter le CO₂ émis par les centrales électriques qui utilisent des combustibles fossiles, et à le stocker dans des aquifères salins ou dans des gisements exploités d'hydrocarbures. Des projets de démonstration déjà en cours et des analyses techniques indiquent que cette mesure est viable. Le CO₂ doit rester confiné pendant au moins 10 000 ans pour que cette option technologique ait un impact climatique. En vue de fournir une évaluation solide des performances d'un site de stockage, à l'échelle de temps indiquée, une approche possible est d'étudier les accumulations naturelles de CO₂. Celles-ci sont en particulier capables de donner des informations sur les interactions roche-CO₂-saumure à des échelles de temps comprises entre le millier et la dizaine de millions d'années. Les champs de CO₂ naturel en mer du Nord (Brae, Miller, Magnus), situés à 4 000 m d'enfouissement et plus, ne montrent pas la néoformation des phases minérales souvent prédite par la modélisation géochimique. La calcite et les feldspaths peuvent constituer encore entre 5 et 20 % des minéraux de la roche, tandis que la dawsonite n'est pas observée. Il en est de même pour des exemples de réservoirs de grès situés dans le sud-est australien et en Arizona. Il est possible qu'un état de déséquilibre thermodynamique se soit maintenu, de sorte que les modèles existants ne sont pas capables de prédire correctement les évolutions minéralogiques réelles, sur les durées pertinentes pour la séquestration du CO₂. Ces modèles nécessitent une meilleure calibration. Les données expérimentales, à l'échéance de quelques mois, ou celles déduites des situations de récupération assistée (CO₂-EOR), à l'échéance de quelques dizaines d'années, sont en général trop courtes pour offrir toutes les calibrations nécessaires. En revanche, les analogues naturels peuvent aider à combler cette lacune. Le plateau du Colorado abrite un tel système naturel, où des gisements estimés à 100 Gm³ de CO₂ ont pu s'accumuler, à partir de sources volcaniques d'âge inférieur à 5 Ma.

L'érosion a porté à l'affleurement l'ensemble des roches et des structures concernées par le système : source, drain, réservoir, piège, couverture. De très gros pièges sont aujourd'hui observables, avec parfois une activité actuelle qui conduit à des sources de CO₂ et à la formation de travertins. Des exemples à Salt Wash Green River, et le long de la faille de Moab, sont brièvement décrits. Ils montrent un phénomène intense de blanchiment de l'hématite avec redépôt local de celle-ci, une cimentation de carbonates avec une signature δ¹³C vers – 7 ‰ autour des zones d'origine du gaz, et des précipitations de silice susceptibles de sceller les zones d'échappement en crête de structure. Une modélisation précise des performances à long terme d'un site de stockage demande une compréhension accrue des chemins et des cinétiques réactionnels au sein des réservoirs et des roches de recouvrement. Il n'y a pas de prédiction vraiment solide à espérer en-dehors de cette approche.

Abstract — Natural Geochemical Analogues for Carbon Dioxide Storage in Deep Geological Porous Reservoirs, a United Kingdom Perspective — Elevated concentrations of atmospheric CO₂ are implicated in global warming. Mitigation of this requires capture of CO₂ from fossil fuel power sources and storage in subsurface aquifers or depleted hydrocarbon fields. Demonstration projects and financial analysis suggest that this is technologically feasible. CO₂ must be retained below ground for 10⁴ y into the future to enable the surface carbon cycle to reduce atmospheric CO₂ levels. To provide robust predictions of the performance of disposal sites at the required timescale, one approach is to study natural CO₂ accumulations, which give insight into rock-CO₂-brine interactions over timescales of 10³–5.10⁶ y. In contrast to geochemical modelling predictions, natural CO₂ fields in the North Sea (Brae, Miller, Magnus, Sleipner), at 4.0 km and deeper, do not show the mineral products which are predicted to form. Calcite and feldspar still comprise 5–20% of the rock, and dawsonite is absent. SE Australian and Arizona reservoir sandstones also do not fit to geochemical predictions. A state of disequilibrium possibly exists, so that existing geochemical modelling is not capable of accurately predicting kinetic-controlled and surface-chemistry controlled mineral dissolution or precipitation in natural subsurface sandstones on the required timescales. Improved calibration of models is required. Geochemical evidence from laboratory experiments (months to years duration), or from enhanced oil recovery (30 y duration) are again too short in timescale. To help to bridge the 10⁴ y gap, it may be useful to examine natural analogues (10³–10⁶ y), which span the timescale required for durable disposal. The Colorado Plateau is a natural CO₂ system, analogous to an hydrocarbon system, where 100 Gm³ CO₂ fields occur, sourced from 0–5 Ma volcanics. Deep erosion has exposed the sediments which formed CO₂ source, CO₂ carrier, CO₂ reservoir, CO₂ trap, CO₂ seal. Some very large CO₂ traps are now exhumed, and some are currently leaking to form cool travertine springs at the surface. Natural examples at Salt Wash Green River, and at Moab Fault are briefly described. These show extensive bleaching of haematite which may be locally redeposited, carbonate cementation δ¹³C –7‰ around point sources, and silica precipitation, which may seal leak-off on buried anticline crests. Accurate geochemical modelling of the long-term performance of CO₂ storage sites, requires improved understanding of CO₂ reaction paths and reaction rates with aquifer reservoirs and with overlying seals. Robust prediction of disposal site performance is not possible without this.

INTRODUCTION

Carbon dioxide emissions have grown during industrialisation of the world (Mackenzie *et al.*, 2001) and are prognosed to increase further. This is linked, by many climate workers, to the observed gradual increase of average world temperature of 0.6°C in the last 140 y. Six scenarios have been highlighted by the IPCC (2001) to investigate the climatic effects if human CO₂ output is altered, or not altered, to meet atmospheric stabilization targets of 350, 450, 550, 650 and 750 parts per million by volume (ppmv). Predictions from a suite of climatic models suggest that the world will warm by 1.4 and 5.8°C, and possibly by 9°C before 2100 as a

consequence of CO₂ and other greenhouse gas emissions (IPCC, 2001). Even if emissions are stabilised, and then reduced at “Kyoto” rates (such that industrialised CO₂ emission is reduced to 5.2% below 1990 levels by 2012 and held at that rate), then the world is already committed to a continued rise of temperature, of at least 2°C over the next 100 y (Wigley, 1998) (*Fig. 1*). Thus short term (100 y) scenarios do not depend much on emissions reduction, but climatic changes after 2100 are greatly influenced by actions taken now to reduce CO₂ (IPCC, 2001), which provide good value for money in avoiding much greater future expenditure (Yohe *et al.*, 2004). These values of average temperature change inevitably disguise local more extreme variations,

such as an increase in south Texas of up to 25°F (14°C) by 2100 (Parmesan, 2001). If these analyses are credible, then the industrialised world must cut CO₂ emissions to about 40% of current values, and develop low carbon emissions industry and energy supply by 2060. This may keep CO₂ levels below 550 ppm, where environmental impacts are predicted to be acceptable, based on scenario A1T reduced fossil fuel use (IPCC, 2001).

Reduction of CO₂ emissions is currently an objective of United Kingdom energy policy (Foresight, 2002; DTI 2003). Multiple options are being pursued, such as improved insulation, energy efficiency, or electricity generation from renewable sources. One of these options is to continue burning of fossil fuels, but to store or sequester the emitted CO₂ and dispose of that below ground in depleted hydrocarbon fields, or in deep saline aquifers (Holloway *et al.*, 1996). Storage of CO₂ in deep geological formations by injection into depleted hydrocarbon traps or regional saline aquifers could hold many years (decades to hundreds of years) of industrial CO₂ generation. This is a particularly attractive possibility for the United Kingdom, which has access to many porous reservoirs and aquifers onshore and offshore, and a broad expertise in the fluid geology of hydrocarbon exploration and production. A CO₂ injection test site is operating offshore of Norway in the Utsira sand. Here, CO₂ derived from condensate production is separated on an offshore platform and reinjected at a rate of 1 Mt/y into the 800 m Utsira sand saline

aquifer. Extrapolating these single-borehole injection rates suggests that just 150 offshore boreholes could satisfy the United Kingdom's CO₂ reduction obligations for Kyoto and beyond to 2020, using many components of proven technology, minimising both development risks and times.

The purpose of disposal is to slow the rate at which additional fossil CO₂ enters the biosphere. At some future geological time, this CO₂ will return to the surface through natural cycling. If this time is less than the recovery time needed for the biosphere, then no net environmental benefit will have been achieved. It is important to estimate the timespan needed for natural processes of CO₂ cycling, to return the anthropogenic CO₂ to its preindustrial level. That is the minimum time needed for subsurface CO₂ disposal. Kheshgi *et al.* (1996) have simulated the recovery time needed (*Fig. 2*). If CO₂ peaks at 550 ppm in 2050, 2 × the present atmosphere level (*i.e.* if CO₂ emissions are halved by 2015), this timespan is 10³ y (IPCC, 2001, scenario A1B). If the rate of CO₂ emission continues to increase on a fossil fuel intensive basis (IPCC, 2001, scenario A1F1), to exceed 1200 ppm by 2175, then the recovery time needed is longer than 10⁴ y. Simulation of CO₂ storage has considered the acceptable retention times necessary to achieve such targets (Lindeberg, 2003) and concludes that CO₂ must be retained for longer than 7000 y. Leakage rates from storage sites must be 0.01%/y or less (Hepple and Benson, 2003) to ensure that CO₂ is stored for a sufficiently long timespan.

Figure 1

The rise of CO₂ since industrialisation has already committed the world to a temperature rise of several centigrade, even if Kyoto agreements are fully enacted (from Wigley, 1998).

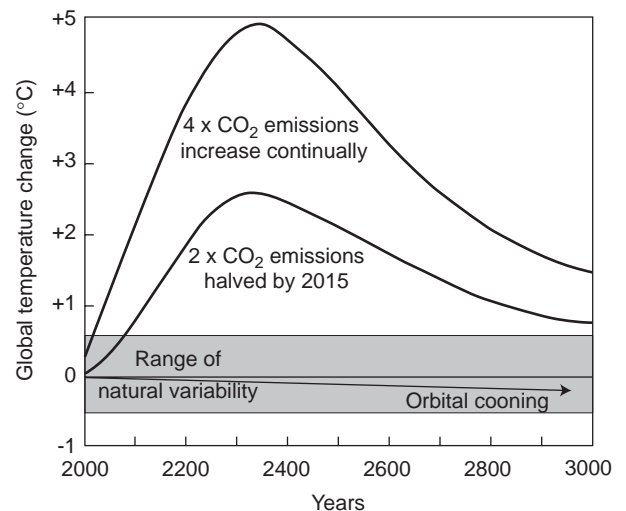

Figure 2

Simulations of temperature rise show that, just as with Figure 1, the world is committed to a continued increase in temperature. This takes many hundreds or, probably thousands, of years to decay back to pre-industrial values (from Kheshgi *et al.*, 1996).

1 UNITED KINGDOM EMISSIONS AND OPPORTUNITIES

Areally extensive and deep sedimentary basins exist both beneath the United Kingdom and offshore of the United Kingdom. The offshore basins are arguably better known geologically than the onshore basins because of intensive hydrocarbon exploration and drilling since 1964 (Glennie, 1998). More than 2000 boreholes have been drilled in the United Kingdom sector alone.

Total emissions by the United Kingdom in 2001 are cited as being 147 Mt/y carbon (565 Mt/y CO₂) (IEA, 2004). An obvious possibility is to consider disposal in offshore or onshore sedimentary basins. The Sleipner field experiment, offshore from Norway, commenced in 1996. Statoil reinject CO₂, produced from a 3 km deep Jurassic condensate, into the Utsira sand a 1.0 km deep saline aquifer (Korbol *et al.*, 1995). It is clearly possible, in engineering terms, to inject 1 Mt/y CO₂ into the subsurface from only one borehole. Consequently, if 150 boreholes could be engineered, then all the yearly CO₂ emissions from all of the United Kingdom coal-fuel power stations could be disposed of (Fig. 3). Injection of CO₂ into depleted oilfields is attractive as a first step—because of both top seal capability and because of the economic side-benefit of extra produced oil. However simple calculation of the limited oilfield volume shows that this can be only a 5-10 y interim measure, hosting a maximum of 2.6 Gt CO₂ in depleted offshore United Kingdom oilfields

(Holloway *et al.*, 1996). Long term storage strategy requires saline aquifers to be used, which have not previously held hydrocarbons or CO₂ for geological timescales. Offshore United Kingdom aquifers could host as much as 240 Gt CO₂, and store 50% of the annual United Kingdom CO₂ emissions for many decades (Holloway *et al.*, 1996).

The costs to a national economy of CO₂ disposal are subjectively considered to be large because of the cost of CO₂ capture at power stations. However analysis by Ash *et al.*, (2002) using United Kingdom Treasury approaches, shows that CO₂ sequestration into deep geological settings is likely to be cheaper than offshore renewable wind power. This implies a small rise of 14% in retail electricity prices, with a national carbon tax being imposed of £31/t CO₂ (Fig. 4). Significantly Ash *et al.*, (2002) calculated that the overall effect of CO₂ taxation was economically neutral to the United Kingdom economy, because of additional employment and economic opportunities created by the new CO₂ disposal industry. The cost would be less than 1% of gross domestic product for the next 100 y, compared to a typical annual growth of 2-3%/y.

2 SLEIPNER EXPERIMENT

Since 1996, at Sleipner West field, the oil company *Statoil* has reinjected CO₂ from the 3.3 km deep mid-Jurassic age Hugin formation into sands and muds of the 1.0 km deep

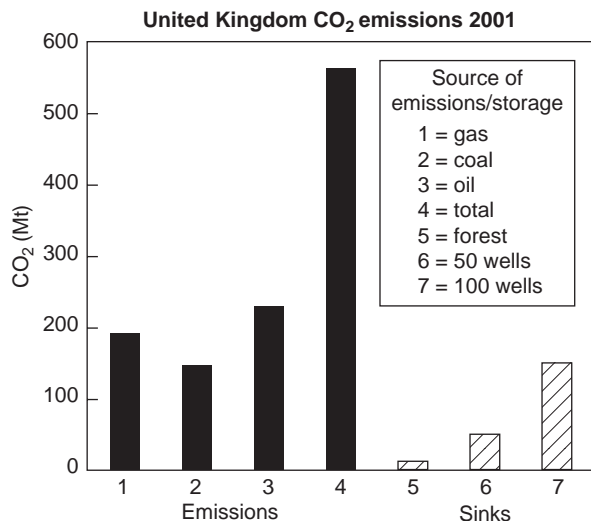

Figure 3

United Kingdom emissions of CO₂ during 2001 totalled about 565 Mt. If several boreholes comparable to that of the Sleipner experiment were engineered, then 150 such boreholes could accommodate the coal-power emissions from all the United Kingdom. This greatly exceeds the potential for doubling the forested area of the UK—which could sequester 11 Mt/yCO₂, but only during tree growth.

Figure 4

Storage of CO₂ is sometimes considered uneconomic because of the additional direct costs involved, mainly of CO₂ capture. However a more complete economic analysis, by Ash *et al.*, (2002), suggests that a United Kingdom carbon tax of £31/t CO₂ would be economically neutral, and provide electricity more cheaply than offshore windfarms.

upper Miocene Utsira formation, which is about 200 m thick (Korbol and Kaddour, 1995). Before injection, this sandstone did not form a natural reservoir for geological accumulations of oil, gas, or CO₂ at this site. This is an archetypal example to investigate the concept of CO₂ disposal into a “deep saline aquifer”. Seismic reflection surveys have been shot across the site in 1994 before any engineered disturbance, again in 1999 after three years of CO₂ injection, and again in 2001 and 2002. By subtracting the results of the series of surveys, it is possible to make images of the net disturbance effect, consequent on the low-density supercritical CO₂ (density about 0.6 g/cm³), filling porespace. These images clearly show that CO₂ remains in the sandstone, although rapid leakage has occurred through intra-reservoir mudrocks (Chadwick *et al.*, 2003).

Figure 5

The experiment of injection at Sleipner retains CO₂ for the first few years of operation. Seismic monitoring surveys by Zweigel *et al.*, (2001) shows that CO₂ has leaked through thin mudstones within the aquifer, but has been retained by the thick top-seal mudrock.

However Zweigel *et al.*, (2001) and Chadwick *et al.*, (2003) show that above the top of the main Utsira sandstone mudrock seal, the seismic difference survey shows small reflectors, similar in amplitude character to those in the bulk of the sandstone resulting from CO₂ injection. This is exactly the type of result to be expected if some CO₂ had already leaked into, and through, a 5 m mudrock top seal into the

overlying 30 m “Sand Wedge”. Processing of the two surveys by Zweigel *et al.*, (2001, Fig. 5) provides a consistent picture that 1 m thick mudrocks within the Utsira formation cannot retain CO₂, only delay its buoyant rise, and neither has the 5 m mudrock formed a robust seal (Fig. 5). There is no evidence that CO₂ has leaked through the main sealing rock of the overlying Nordland Group mudrocks. However, no natural CO₂ accumulations exist at shallow depth in the North Sea, so there is no natural analogue evidence to show how this particular mudrock seal may perform over geological timescales. Additionally, geomechanical modelling simulation of mudrock top seals performed at Lawrence Livermore laboratories, and presented by Johnson *et al.* (2003), suggests that thin mudrock top seals will be prone to fracture in the initial stages of containing a buoyant CO₂ fluid column.

Chadwick *et al.*, (2003) show that CO₂ injection has formed a vertical chimney, within the Utsira formation sandstones and mudrocks, of increased relative permeability. This points to physical leakage through thin mudrock seals being a short-term (decades) problem for saline aquifer disposal. This is not necessarily fatal to the promising concept, but is a problem which needs to be assessed and quantified. At present the question remains—will leakage occur at all through the mudrock top seal, and if so at what rate? Using the logic of Hepple and Benson (2003), a leakage rate of less than 0.01%/y means that zero leakage must be detected at the Utsira formation injection site until 2005, and to confirm less than 0.001%/y leakage, then no leakage must be detected until 2023 (Chadwick, pers. comm., 2004). Either of these target leakage rates, if durable over millenia, would be successful for long term storage.

Over longer timescales of 10²-10⁵ y, will there be geochemical interaction between the CO₂ saturated aquifer waters and the overlying mudrock? In many fluid migration systems there is a possibility that “fingering” of interaction may occur, to produce fluid breakthrough at much shorter timescales than equilibrium predictions would suggest. It is not known how CO₂ will interact on these timescales with the reactive shallow-buried smectite clays of the Utsira formation and similar top seal mudrocks in the North Sea and other sedimentary basins. Modelling by Johnson and Nitao (2003) suggests that geochemical reaction will occur on timescales of 1-120 y to reduce mudrock seal permeability. However initial geological investigation by the present authors of rock mineralogy in North Sea examples does not confirm the suite of predicted minerals.

3 PREDICTED MINERAL REACTIONS

CO₂-induced reactions, particularly in brackish or saline fluids (Shmulovich *et al.*, 1995), are likely to involve acid hydrolysis of rock-forming minerals; for example: anorthite + 2H₂O + CO₂ → kaolin + calcite. Studies of CO₂ interaction

with reservoirs have used computer simulations (Gunter, 1996; Knauss *et al.*, 2001; Johnson and Nitao, 2003), indicating that feldspars and micas are potentially very reactive to CO₂ on timescales of 10-400 y. For example, with trace (ppm) CO₂, feldspar + clay + CO₂ → [laumontite/prehnite/chlinochlore] depending on salinity and cations present. However, laumontite and other zeolites are unstable in CO₂ concentrations more than tens ppm, so that: feldspar + clay + CO₂ → kaolin + muscovite + carbonates + quartz. More recent analyses have predicted dawsonite to be the stable carbonate formed (Knauss *et al.*, 2001). Simulations of clay mineral interactions have been less sophisticated, often due to the lack of specific thermodynamic data. (Gunter *et al.*, 1996) found that glauconite clay (annite as a proxy) dissolved 5-10 times more rapidly than feldspar, to produce siderite and muscovite. Thus smectite and glauconite clays would be expected to be amongst the most reactive.

Autoclave laboratory experiments have not confirmed this theoretical modelling, because elevated temperatures reduce CO₂ solubility, whereas realistic lower temperatures greatly decrease reaction rates to unfeasibly long timescales. We are not aware of any definitive field study of an *in situ* natural CO₂ reservoir to confirm the modelled predictions. Some mineral and petrographic data has been report from CO₂ springs in Arizona, which suggests that stratabound layers of high CO₂ concentration may control the occurrence of dawsonite, for example (Moore *et al.*, 2003). In the Otway Basin, CO₂ has charged the Ladbroke Grove field less than 1 Ma ago with 26-57% CO₂, dissolving rock fragments, calcite, chlorite and producing kaolin, quartz and small concretions of Fe+Mg-carbonate above the GWC from lithic sandstones. By contrast, the adjacent Katnook field has no CO₂, and retains feldspar, rock fragments, chlorite and calcite.

This is problematic for predictive modelling, because it is apparent that natural systems are certainly greatly influenced by a suite of “kinetic” factors. Computer models of low temperature processes are based on combinations of kinetic rates of precipitation and dissolution, and equilibrium. The choice of kinetic constants and pathways is difficult, as these factors vary with mineral solid solution, aqueous fluid composition, mineral microsurface area, and brine salt content. Consequently, nature may differ from modelling. This is important because growth of these different minerals can reduce, or enhance, rock porosity and permeability—and thus improve or worsen CO₂ retention in a sequestration setting. Geochemical modelling results typically predict different mineral assemblages to occur with:

- different CO₂ concentrations;
- different rock mineralogies;
- different reaction times.

Studies of mineral weathering at the earth’s surface can be used as analogous processes—with varying CO₂ content and mineral-to-water ratio. Many authors have highlighted observations that natural weathering rates over thousands of years, or much longer duration, are very significantly slower than

mineral reaction rates derived from experiments on unweathered material (Annbeek, 1992; Velbel 1993; Lee *et al.*, 1998). White and Brantley (2003) showed experimentally that weathering rate in CO₂ rich waters decreases exponentially, as a power-law rate, with duration of weathering, for plagioclase and for other major rock-forming silicates. Experimental reaction rates are several orders of magnitude faster than rates derived from nature. Consequently, rates derived from laboratory experiments are only a general guide to rates in natural systems, not an exact guide. Laboratory rates are always faster than rates for naturally weathered minerals, usually by a factor of 10², and as much as 10⁶ in short term experiments (days or weeks). The importance of this is that the rapid rates of mineral reaction and CO₂ sequestration predicted by modelling do not fit observations of real CO₂ aquifers, so that prediction of rapid mineral precipitation will be unreliable. However the long-term dis-equilibrium of minerals with CO₂ observed in real aquifers is very compatible with the processes measured by White and Brantley (2003).

Geochemical interactions between CO₂ (aq) and rock forming minerals are very likely to occur, involving both dissolution and precipitation. The problem is to understand, and predict the rates and mineral products of these reactions at the low temperatures prevailing in CO₂ disposal (30-100°C). At such low temperatures, predictions from equilibrium thermodynamics are unreliable. Overall reaction sequences at cool temperatures are dominated by influences such as: reactive surface area, age of reactive surface, grain coating, grain micro-porosity, low fluid-to-mineral ratios. The final effect can be kinetically slow weathering close to thermodynamic equilibrium. Modelled predictions can differ greatly from reality. For example, it has already been noted that the dawsonite predicted by geochemical models (Knauss *et al.*, 2001) does not occur widely in nature, and further natural examples from CO₂ rich oilfields (below) show that in many cases dawsonite, or zeolites, have not been identified at all. Particularly important are the rates of reactions. For example these may determine if kinetically-rapid dissolution of mineral (A) may outpace equilibrium-favoured precipitation of mineral (B). It is notable that overall rates of reactions depend greatly on the experimental dataset used within a geochemical model, whereas rates of weathering at cool temperatures in nature may be 10⁶ times slower. Being able to demonstrate robust prediction of reaction routes and rates is a key problem, if CO₂ sequestration within minerals is to gain industrial-scale acceptability with government regulators.

One route to demonstrating that geochemical models can make valid predictions into the future, is to calibrate modelling softwares against natural CO₂ systems which have been active for the required 10⁴ year timescales. When a model can reproduce a known natural system, it can then be validated against a different, but related, natural system. If successful, then the model can form a useful predictor, suitable for evaluating CO₂ retention or leakage.

Figure 6

The North Sea contains several hydrocarbon fields with naturally high CO_2 , ranging 15-60 mol%. These are all positioned in the southwest Viking Graben, with the eastern being Sleipner. Mineral cements in these sandstone aquifers show little to no sign of interaction or equilibration with CO_2 over millions of years.

4 NATURAL EXAMPLES: UNITED KINGDOM OILFIELDS

Several fields in the United Kingdom offshore (*Fig. 6*) are known to contain naturally high contents of CO_2 . A grouping of fields all contain high CO_2 : South Brae (35 mol%), Central Brae (30 mol%), Miller (50 mol%), Kingfisher (14 mol%), Tiffany, Toni, Thelma (10 mol%), (Fletcher, 2003a, 2003b; Gambardo and Donagemma, 2003; Spence and Kreutz, 2003; Baines and Worden, 2004) and the adjacent Sleipner west (9%), site of the Norwegian injection experiment (Ranaweera, 1987; Korbol 1995). The Brae and Miller fields have been studied petrographically by McLaughlin *et al.* (1996), Marchand *et al.* (2001). Miller comprises 68% quartz sandstone, with 10% lithics, 5% feldspar. Cements are shallow burial calcite cement (5%) retained in concretions, extensive quartz cement (10%), with minor late dispersed calcite (2%) all values include porosity. The late carbonate cement has a potentially distinctive signature of $\delta^{13}\text{C} -8\text{‰}$ (Baines and Worden, 2004). This is similar

to $\delta^{13}\text{C} -7\text{‰}$ values considered to represent upper mantle degassing CO_2 (Galimov, 1968; Fuex and Baker, 1973).

The Magnus field (Macaulay *et al.*, 1992, 1993) has only 2 mol% CO_2 in the hydrocarbon zone, is a 65% quartz sandstone, with 16% feldspar, 3% lithics, cemented by 4% quartz, 8% carbonate 4% clay. The carbonate is shallow to mid burial with isotopic signatures of $\delta^{13}\text{C} -12\text{‰}$.

A brief report of Sleipner Vest petrography by Ranaweera (1987), states that the mid-Jurassic Hugin Formation CO_2 sandstone contains orthoclase, microcline and plagioclase feldspars, with minor lithic volcanic and granitic grains, and even altered glauconite. Again, this is not a mineral assemblage in equilibrium with high CO_2 porewater—especially as the experiments of Gunter *et al.*, (1996) suggested that glauconite would react within a very few years.

Significantly, neither Miller, Magnus, nor Sleipner Vest fields show present-day evidence of extensive dissolution of carbonate from a CO_2 charge, zeolites or dawsonite have not been identified in any field, and K-feldspar co-exists with CO_2 at the present day. No field has precipitated extensive deep burial carbonate cement as a result of CO_2 being sequestered by natural processes. All of these effects appear to be out-of-equilibrium with the significant CO_2 contents and history, even though present day burial temperatures are about 100°C - 120°C . It is possible that equilibrium geochemistry is not the dominating factor in predicting CO_2 sequestration reactions.

5 NATURAL EXHUMED EXAMPLES: COLORADO PLATEAU

The uplifted Colorado Plateau area of the United States contains a natural CO_2 basin system, where zones of CO_2 input, regional migration in saline aquifers, ancient CO_2 traps, and modern CO_2 leakage up faults are all exposed today in 3D. The Colorado Plateau of the United States (*Fig. 7*) hosts many giant accumulations of CO_2 at the present day (Allis *et al.*, 2001). The sandstone aquifers of this foreland basin, and their mudrock seals are uniquely uplifted and dissected by canyon erosion. The CO_2 system has probably been active for 5 Ma, and may have been active for 15 Ma, and is still active today. Within this exhumed regional system, we can choose specific locations (*Fig. 8*) enabling us to examine and sample the effects of the CO_2 -rock-water geochemical system at several structural levels.

We make analogy with the concept of “hydrocarbon systems” (Magoon and Valin, 1994) within sedimentary basins, where it is possible to define: hydrocarbon source, timing, migration route, reservoir and leakage. In Colorado, we are examining a CO_2 system, to locate CO_2 sources, examine migration routes, and can examine traps, reservoirs, and seals which contain hydrocarbon + CO_2 + brine, and contrast those with sites which were exposed simply to CO_2 + brine.

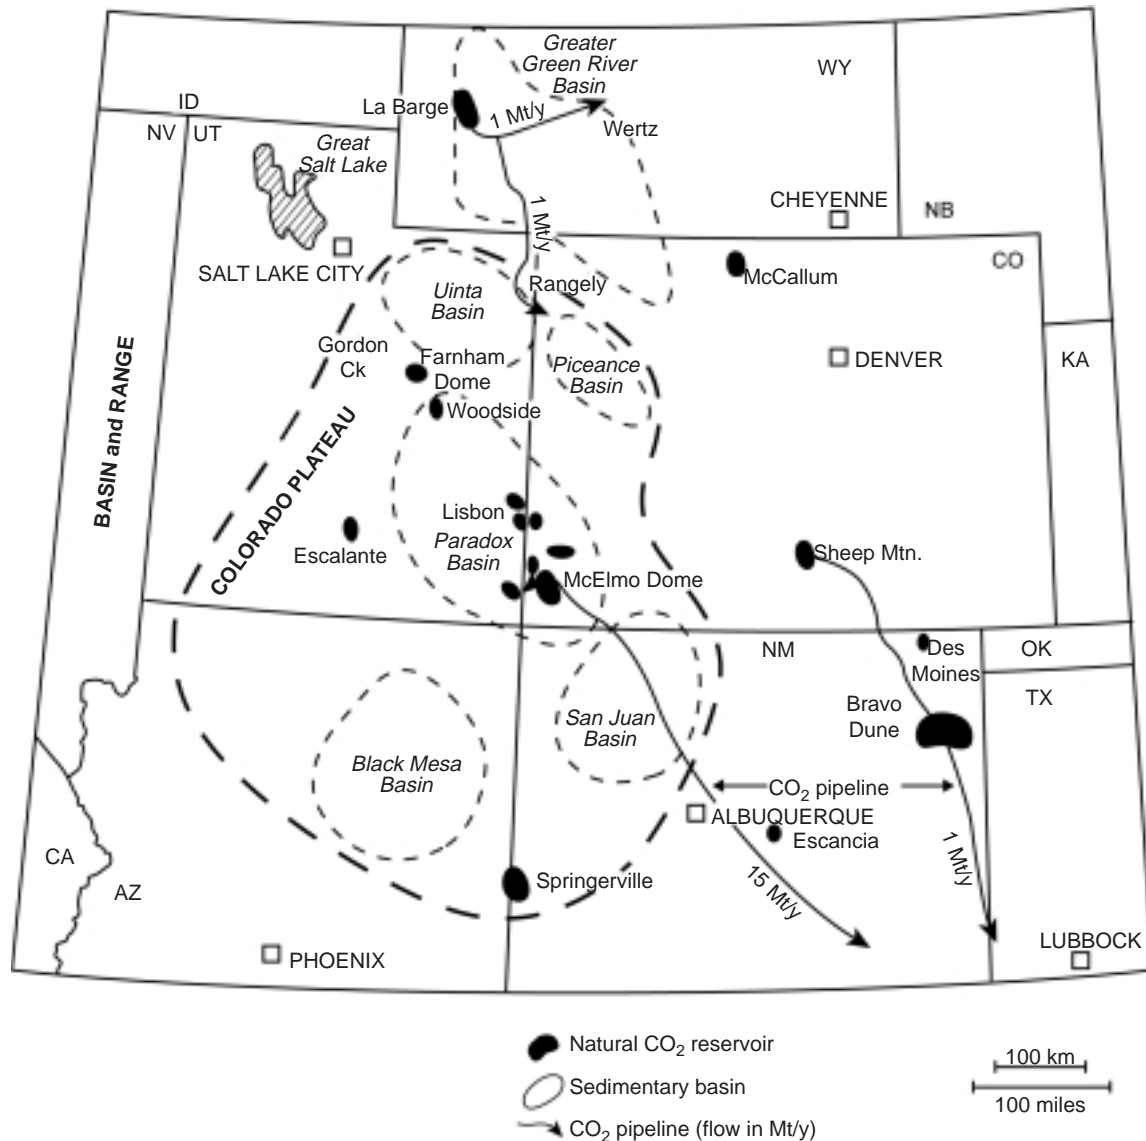

Figure 7

The Colorado Plateau of United States is anomalous in hosting many very large natural accumulations of CO₂. This region is here viewed as a “CO₂ system” where CO₂ + mantle helium are supplied by recent volcanism derived from the upper and deep mantle (from Allis *et al.*, 2001).

5.1 Geological Setting

Because of epeiric uplift of the Colorado Plateau in the past 5 Ma, kilometres of erosion have occurred to expose the sediments; regional deformation is minimal, and the fundamental geological history is well-known (Hintze, 1988; Stokes, 1988). The Mesozoic stratigraphy is similar in the adjacent states of SE Utah, Arizona, Colorado and Wyoming (Fig. 9). During Cambrian to Mississippian times Utah and Arizona accumulated sediments on the passive western continental margin of Laurentia. This was disrupted by the Devonian Antler Orogeny accretion of an island arc, which thrust

deepwater sediments eastward. Carboniferous sediments accumulated in a NW-SE depocentre adjacent to the Uncompahgre basement uplift of the “ancestral Rockies” formed by the Alleghanian Orogeny collision of Laurentia and Gondwana. South-east Utah is underlain by the Paradox Basin, where thick Pennsylvanian salt, and multiple oil source rocks (Huntoon *et al.*, 1999), accumulated. As east-dipping subduction commenced, Mesozoic sediments accumulated as layer-cake stratigraphy in a NNE-SSW foreland basin, interrupted by the microcontinent accretion in the Sonoma and Nevadan Orogenies. The Sevier Orogeny associated with the largest compression, by accretion of the Sierra

Figure 8

The Colorado Plateau is a minimally-deformed block of Mesozoic sediments, bounded to the west by active Basin and Range extension, and to the east by the Rio Grande Rift. This rift formed by clockwise rotation of the Colorado Plateau, and dissects Mesozoic Rocky Mountain uplifts. The Paradox Basin contains Carboniferous oil source rocks, which possibly supplied tar sands in south Utah. The Uinta Basin contains Eocene source rocks for oil, which migrated vertically, and possibly southwards. Numbers refer to CO₂ spring localities discussed in the text: 1, Salt Wash and Crystal Geyser; 2, Moab anticline; 3, Grand Canyon; 4, Springerville.

arc, formed folds and thin-skin thrusts as far east as Wyoming. Foreland basin sediments deposited during this early Triassic-end Cretaceous period are targets for study, as they form laterally persistent beds for tens kilometres, which could act as regional carrier beds for hydrocarbons, CO₂ or H₂S. During the final stages of the Sevier episode, “Laramide” thick-skin tectonics caused relative uplift of basement blocks (Hintze, 1988 (*Fig. 8*)) in the Sevier foreland. These produced large open antiform growth structures, on a tens km scale, which are today expressed as large reverse-faults or monoclines (*Figs. 8 and 10*). These subsequently acted as very large (super-giant?) traps for CO₂, and possibly for hydrocarbons (Beitler *et al.*, 2003), which have been exhumed due to subsequent Colorado Plateau uplift. The Uinta Basin overlies a late pre-Cambrian aulacogen (Stokes, 1986), and formed by 7.6 km post-Cretaceous subsidence adjacent to one such uplift, generating oil from the

world-class Eocene Green River formation. Oil has also been generated in the Paradox Basin from a suite of source rocks, ranging from Pennsylvanian Phosphoria formation, through lower Cretaceous marine Mancos shale and upper Cretaceous shoreline deposits of the Mesaverde Group. Oil migrated radially away from the Uinta depocentre and may have moved regionally southwards into this study area (Stokes 1988, *Fig. 13.1*)—also forming vertical bitumen dykes (locally known as gilsonite) by vertical overpressure leak-off along the Uinta axis. Oil migration, possibly from a number of source rocks (*Fig. 9*) has formed small subsurface fields, surface seeps around the eroded basement uplifts (breached traps), and the supergiant field, now expressed as surface 7 Gbbl Tar Sands in uppermost Permian sandstones of southern Utah (Huntoon *et al.*, 1999). This was probably derived from the Mississippian Deseret Limestone within the local Paradox Basin, and migrated via the Permian White

Figure 9

Simplified stratigraphic column of post-Cambrian lithologies and Formations in the Moab area. Modified from Hintze (1988). Similar stratigraphy, with local variations, exists in the Colorado Plateau region. The column also shows stratigraphic locations of oil shows, world-class tar sands, and regionally bleached sandstones.

Rim sandstones as carrier beds in the mid Tertiary. Another tar sand, possibly with 12 Gbbl of oil occurs in the overlying Hoskinnini Member of the Triassic Cutler Group (Fig. 9). Post-Triassic movement over pre-salt basement lineaments have produced large fault and antiform structures in the Paradox Basin. Some of these formed CO₂ traps, which are now exhumed at the surface in 3D, and may have also hosted some hydrocarbon (see also Beitler *et al.*, 2003).

Explosive dacite and rhyolite volcanism occurred in western Utah from 40-15 Ma, related to plate subduction on the western United States. Renewed volcanism, of alkali-basalts, together with lamproites, has occurred from 5-0 Ma (Hamblin, 1994). It is this rift volcanism, which we consider to supply present-day CO₂ and He accumulations. This province is unusual because of its giant CO₂ accumulations (Allis, 2001), the largest CO₂ field in Utah is Escalante, with 100 Gm³ (4 tcf), comparable in volume to the North Sea Leman gasfield, and Bravo Dome CO₂ accumulation in New Mexico contains 200 Gm³ (8 tcf) recoverable CO₂ (Roberts and Godfrey, 1994).

The Colorado Plateau has been uplifted by 2 km in the last 6 Ma (Pederson *et al.*, 2002), and crust has thinned to the west by extension, producing the Basin and Range province. Rotation of the Colorado Plateau clockwise has enabled opening of the Rio Grande Rift east of the Plateau. Faulting along basement structures within the Plateau has produced very large (km throw) normal and monoclinical structures; faulting continues to Quaternary time, shown by faults cutting radiometrically-dated lavas at Vulcan's Throne in the Grand Canyon.

5.2 Cool Springs, Helium, and Travertines

CO₂ has been, and is, leaking off after migration into deep traps. Erosion of the plateau has enabled CO₂-bearing brines to drain vertically and laterally into rapidly eroded canyons. These effects produce cool CO₂ springs, with abundant travertine. At the north and west of the Plateau, a suite of such springs at Salt Wash, Green River (Baer and Rigby, 1978) exhale saline water with CO₂ and minor H₂S. Heath (2003) and Shipton *et al.*, (2005) show that waters are very saline 13.8-21.2 eq wt%, diluted in near-surface aquifers by by modern meteorically-derived waters. 95-99% of the gas is CO₂, with minor N₂, Ar, He and H₂S. He values of R/Ra are 0.302, indicating a crustal component.

To the south and east of the Plateau, Crossey (2002) has examined modern waters from cold seeps in the Grand Canyon (3 on Fig. 8), which precipitate extensive travertines in association with limestone/shale contacts and basement faults. Analyses of ³He/⁴He ratios with 0.15 R/Ra show a mantle signature, ⁸⁷Sr/⁸⁶Sr values show radiogenic ranges from 0.710 to 0.728, and δ¹⁸O of water is meteoric. A mixing can be envisaged of shallow active groundwater flow, with deeper "old" waters carrying CO₂; these become enriched in

Figure 10

Cartoon sketch section across the Colorado Plateau, from north to south. The Tertiary Uinta hydrocarbon basin forms the northern limit and the Grand Canyon the present southern limit. Deep-sourced volcanic CO_2 migrates vertically through reactivated basement structures with mantle He signatures, then is captured by horizontal sediment layering to migrate laterally through aquifers, with crustal helium signatures. CO_2 may dissolve deep carbonates to super-saturate formation waters which form cool springs with abundant travertine at the surface.

CaCO_3 by dissolution of limestone, and so precipitate travertine at spring sites. Travertine U-series ages range from modern, to older than 350 ka. The Colorado Plateau is abnormally rich in He with many gas fields containing 5-10%, and up to 37 Gm^3 (1.5 tcf) of He in individual fields. The geological setting suggests that the origin of this He is from intrusive volcanics (Casey, 1983). Current work shows He isotope ratios with unmodified mantle signatures (Phinney *et al.*, 1978, Ballentine, pers. comm., 2003). This is taken as evidence that basaltic volcanism is contributing CO_2 and He to the active present-day basin system. Ballentine *et al.*, (2001) have examined He accumulations associated with CO_2 fields in west Texas. These fields are not on the Colorado Plateau, but lie in the foreland to the Alleghanian Orogeny. They show that He can act as a tracer of CO_2 origins. Using He/ CO_2 ratios they model diffusion to show that in some cases, CO_2 is retained for geologically very long periods of 300 Ma.

5.3 Bleached Sandstones and Large Scale CO_2 Fluid System

Ancient regional migrations of fluids have occurred in the Plateau area. We use four lines of evidence to suggest that the water and $\text{CO}_2 + \text{H}_2\text{S}$ migration has occurred and oil migration may have followed similar carrier bed routes.

Firstly, the Plateau area is noted for its red-bed sandstones, which have been diagenetically bleached (Chan *et al.*, 2000)

along permeable zones (Figs. 11 and 13). In normal red-bed sandstones, iron exists as oxidised red Fe^{3+} , which is poorly-soluble in aqueous fluids. This needs to be geochemically reduced to much more soluble Fe^{2+} to enable its aqueous transport. This means that reducing fluids have enabled the oxidised red iron to become soluble, and to be removed from the sandstone. In contrast to previous studies, we do not consider that such bleaching is produced directly by hydrocarbons—as we know of many red-coloured sandstones, which act as reservoirs for North Sea oil. An additional geochemical aspect is needed. We consider that H_2S , commonly associated with CO_2 in many of the modern springs, has reduced the iron and bleached the rock, this could originate from deeper thermal sulphate reduction. Organic acids or CO are also feasible reductants. Some iron is re-deposited locally as Fe and Mn oxides (Chan *et al.*, 2000). However some thick aquifer sandstones, such as the 200-670 m aeolian Navajo, are so extensively bleached without local oxide growth, that they are incorrectly considered to be depositionally white. For example the 600 m Navajo sandstone is recorded to be red at its base in Zion Park, becoming progressively more white to its top 200 m (Biek *et al.*, 2000, Fig. 4). Using satellite imagery it is possible to see bleached “migration fairways” in the regional Navajo sandstone where geochemically reducing fluids have entered structural highs “anticlines”, which are now partly eroded (Beitler *et al.*, 2003). Regional fluid flow must have effected mass-transport of iron.

Figure 11

Little Grand Wash, Utah, showing line of fault with bleached mudrocks along its outcrop. Southern (downthrow) side is to right. Harder mounds are extinct travertine mounds about 10 m diameter.

Secondly, there is an almost total lack of bitumen residue. Although some oil has certainly migrated through these rocks, we consider this to be strong evidence of a natural CO_2 drive producing natural “enhanced oil recovery” which dissolved any bitumen, to leave very little trace of residual hydrocarbon. We do not claim that bitumen is entirely absent – there are well known Tar Sand deposits in southern Utah (Huntoon, 1999), which contain up to 16 Gbbl oil in White Rim sandstones, and there are also bitumen veinlets along the Moab fault. However compared with other exhumed hydrocarbon basins in the United Kingdom or United States, bitumen is, for some reason, lacking.

Thirdly, regional carrier beds can be inferred for $\text{CO}_2 + \text{H}_2\text{S}$, these are beneath mudrock seals. These form stratabound zones of white sandstone 1-2 m thick at the top of aeolian or fluvial red-bed sandstone units, with no depositional facies differences. These are the famous “White Rim” sandstones around canyon tops (Stokes, 1988). Excellent exposures show that these white zones are laterally extensive (tens kilometres), and underlie less-permeable sediments, which would have formed top-seal to laterally migrating low-density gas + water mixtures. We interpret such bleached sediments to be the diagenetic traces of regional carrier beds, analogous to carrier beds of similar extent and thickness inferred in conventional hydrocarbon systems. Diagenetic studies have shown hydrocarbon-filled fluid inclusions in diagenetic dolomite occur in these carrier beds, and suggest that any oil was derived from Mississippian source and emplaced about 44 Ma (Huntoon *et al.*, 1999).

Figure 12

Crest of Moab anticline looking south, shows partly bleached red-bed sandstone, with left dipping surface in mid-distance defining a crestal fault block. Horizontal colour change, with white sandstone above, marks paleo-fluid contact. Several fault blocks are visible, each with a paleo-fluid contact, all sited on the anticlinal crest, within Entrada Sandstone (Moab Tongue Member).

Figure 13

Crest of Moab anticline looking north, showing abundant chert replacement of calcite limestone in mudrocks directly overlying the anticline crest. This may be a position of paleo-leak-off vertically. Person stands on 4 m diameter mound, with similar chert mound 10 m to left. The Entrada sandstone is bleached white in the 2–4 m below overlying Tidwell Mudrock seal, which is overlain by Salt Wash Sandstone. Inset pictures show (left) detail of vertical section where chert replaces limestone; (right) detail of plan section where chert replaces limestone.

Fourthly, isotope signatures in diagenetic carbonate cements from these bleached sandstones are unlike those known to form from oxidation of hydrocarbon. Hydrocarbon oxidation produces signatures of $\delta^{13}\text{C} = -30\text{‰}$ (Macaulay *et al.*, 2000). Isotopic signatures in Colorado bleached sandstones are seldom lower than $\delta^{13}\text{C} = -10$ (Garden *et al.*, 2001; Chan *et al.*, 2000), which is compatible with an origin from organic acids, or mantle CO_2 , but not hydrocarbon. These $\delta^{13}\text{C}$ values do not fit with the prediction that hydrocarbon oxidation caused iron reduction, to remove the iron from bleached sandstones. By contrast, these $\delta^{13}\text{C}$ values are consistent with calcite produced by interaction with mantle CO_2 , in a process similar to the late calcite cement in the Miller North Sea oilfield (above).

6 MODERN CO_2 LEAKAGE UP FAULTS

6.1 Salt Wash, Utah

These sites (labelled 1 on *Fig. 8*) occur south of the town of Green River in SE Utah, and have been reported by Shipton *et al.* (2005), Heath *et al.* (2003), and briefly investigated by the present authors. A number of sites occur with CO_2 emissions at modern cool saline water springs, associated with small-throw east-west normal faults and their intersection with a north-plunging open anticline. The modern springs are expressed as travertine mounds, one is active today adjacent to the Green River, where the fault line is very well exposed.

A further five are active in the Great Salt Wash. At each locality a number of inactive ancient travertine mounds occur, typically 5 m thick and 20 m diameter, spaced along the fault (*Fig. 11*). Each travertine has been fed by a vertical 300 mm wide calcite vein, which turns horizontal within 4 m of the paleo-surface—suggesting a fluid pressure control. The final stages of veining form as aragonite indicating lower CO_2 content, or poisoning by SO_4 or Mg (Morse and Mackenzie, 1990). We consider that these springs are the shallowest expression of the CO_2 basin system, and represent lateral migration through sandstone aquifers. Extensive bleaching of red sandstones and mudrocks occurs, with complete pore-filling passive calcite cementation of sandstones around carbonate veins and travertines. Cementation decreases laterally away from each spring site, giving the opportunity to evaluate the effects of $\text{CO}_2(\text{aq})$ -rock interaction at decreasing fluxes. At these cool near-surface temperatures it is probable that kinetic factors in mineral reactions play an increased role in the fluid-rock interactions at this fault-scale. Mudrocks within the fault zone and overlying shale are multicoloured, or contain bleaching cross-cutting bedding, suggesting post-depositional alteration (*Fig. 11*). Mudrock smear, 500 mm or thicker, exposed along the fault plane would conventionally be considered to seal a fault plane to fluid movement—however saline water + CO_2 have obviously succeeded in finding or making a permeable pathway.

6.2 Springerville-St Johns Arizona

An extensive complex of CO_2 springs has been reported by Moore *et al.*, (2003), these are leakage through the crest of a NW-trending faulted anticline, controlled by basement structure (4 on *Fig. 8*). CO_2 is reservoirised in a series of Permian sandstones, limestones and dolomites. Extensive travertines occur over 250 km², with kaolin precipitation and rare dawsonite. Several cool springs are active at the present day. Deposits are younger than Quaternary basalt and are interbedded with Pleistocene river gravels, so may date from 1 Ma ago.

7 ANCIENT CO_2 PALEO-TRAP: MOAB ANTICLINE

This site lies north of the town of Moab in SE Utah, where salt movement in the Paradox Basin has formed faulted anticlines along basement fault trends affecting Triassic and younger sediments (2 on *Fig. 8*). The exceptionally well-exposed Moab fault and Moab anticline, are directly comparable in scale to subsurface hydrocarbon and CO_2 structures on the Colorado Plateau at the present-day. The Moab fault is sometimes mapped as a south-east extension of the Salt Wash fault where CO_2 is leaking at the present-day (above), and has been investigated by Garden *et al.* (2001) and the present authors.

Garden *et al.*, (2001) interpreted the Moab Anticline to be an exhumed paleo-hydrocarbon reservoir where palaeo-fluid contacts are revealed by horizontal colour changes cross-cutting bedding (Fig. 12). We agree with their interpretation that palaeo-fluid contacts are recorded, but consider that CO₂ also had a vital influence. This is shown by four lines of evidence.

Firstly, the carbon isotope signatures of calcite cements are similar both to those from CO₂ cements in Miller oilfield North Sea, and those cited by Chan *et al.*, (2000) from Utah. These are typical of mantle carbon values, not oxidation of hydrocarbon, as discussed above.

Secondly, the excellent surface exposures enable the morphology of carbonate cements to be traced out. These form unusual pipes within the sandstone body, extending up-dip from breached faults Garden *et al.*, (2001). This is exactly as would be expected for up-dip buoyant leakage of CO₂ charged waters. However this is a most unusual morphology for burial or hydrocarbon-related cements, which are usually concretionary or uniformly dispersed. Vertical pipes, which are cemented by haematite, are recorded by Chan *et al.*, (2000) on the Moab anticline below the bleaching contact. These could represent the density-driven convection of CO₂(aq) waters derived from the structure crest. Numerical simulation of convection density overturn in porous media CO₂ storage has been portrayed by Ennis-King and Peterson (2003).

Thirdly, the complete lack of bitumen, or dead oil, throughout the reservoir or at inferred palaeo-oil-water-contacts. This implies either that oil was never present, or that extremely efficient dissolution of bitumen in the reservoir occurred by CO₂ fluids.

Fourthly, there is unusually extensive chert cementation, which selectively replaces limestone in the topseal mudrocks, but only on the crest of the anticline. Structure crests, such as this, are well-known to be the preferred positions of leak-off for buoyant hydrocarbons, or for geopressured fluids in deeply-buried hydrocarbon systems (Darby *et al.*, 1996). We interpret the locations of chert at the Moab anticline, to be a record of vertical leakage of CO₂-charged fluids through fractures at the crest of the structure (Fig. 13). Elsewhere at this stratigraphic horizon, sparse chert is known to occur, but is volumetrically minor (Hintze, 1988, Koeberl *et al.*, 1999), so this anticline crest is anomalous. The localization of chert precipitation could be due to CO₂ rich saline water experiencing a pressure drop upon breaching the mudrock seal overlying the geopressured sandstone reservoir. This process is known in several hydrothermal systems containing volcanic CO₂, such as Broadlands (Simmons and Browne, 2001). It is also possible that silica precipitation processes may be controlled by salt-in and salt-out effects. These have been established during experimental studies of H₂O-CO₂-brine systems at higher P and T. Crucially, these effects can not be predicted by most of the existing geochemical modelling codes. The fluid system NaCl/CaCl₂-CO₂-H₂O ± oil shows that one homogeneous fluid exists at higher

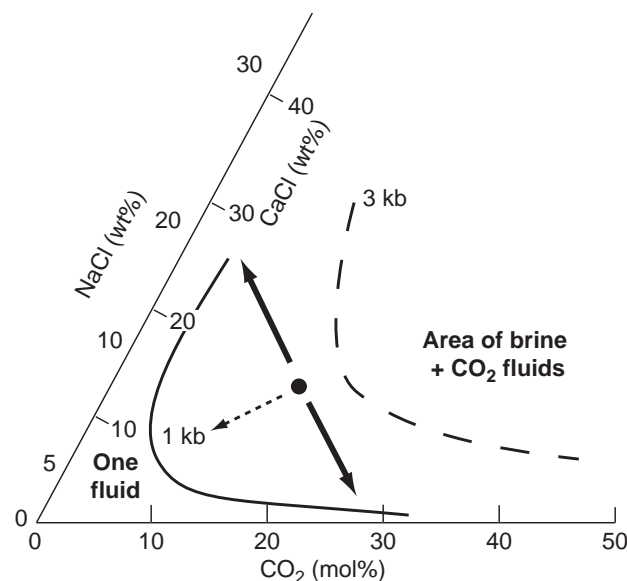

Figure 14

Phase relations in the CO₂-brine system. When pressure drops the pore-filling fluid composition (•) un-mixes with each component following the arrows. This produces CO₂ gas (which cannot carry dissolved SiO₂), and brine with greater salinity (also with less SiO₂ solubility). Thus silica can be forced to precipitate if pressure decreases—for example during leak-off from a geopressured trap into overlying normally-pressured sediment. This is one possible mechanism for chert precipitation at Moab anticline crest.

pressures. If pressure decrease occurs, by vertical leakage of fluid from a geopressured trap, then the phase boundary moves across the original mixture composition, and consequently exsolution results, to form CO₂ gas and brine (Fig. 14). In both the CO₂ gas and exsolved brine, the weight percent water is reduced so that SiO₂ solubility decreases and silica will precipitate. The effect is enhanced if the brine becomes Ca-enriched (due here to host-rock change from mudrock to carbonate). Preliminary 1 kb, 400°C experiments show that silica solubility is greatly enhanced by dissolved Na₂SO₄. Both of these processes may be capable of self-sealing leakage from geopressured CO₂ sequestration reservoirs.

CONCLUSION

- Storage of carbon dioxide emitted by fossil fuel use is essential to reduce future global warming. This can be undertaken in deep geological aquifers. Timescales of 10⁴-10⁵ y are needed for robust containment. This will require some monetary value to be given to CO₂, but can be economically neutral on the United Kingdom economy.

- An industrial scale experiment at Sleipner to inject CO₂ into an aquifer 1000 m beneath the North Sea shows that existing oilfield technology is adequate. However the long-term performance of this storage site is not yet demonstrated. Monitoring shows leakage through thin mudrocks, even though the main seal remains robust.
- Natural analogues from North Sea oilfields show that high CO₂ contents at > 4.0 km can be retained for geologically long periods of time. However the rock and fluids appear to be out of chemical equilibrium. This suggests that geochemical modelling softwares may need improved calibration to make accurate predictions at the timescales involved in nature.
- Natural analogues for CO₂ migration, sealing, trapping and leakage occur in the United States Colorado Plateau. This enables study of exhumed carrier beds, exhumed reservoirs, and present day leakage associated with faults. Quantification of mineralogical changes at such sites may assist geochemical models to be calibrated to long natural time scales.
